ABSTRACT. We investigated how forest structure affects the occurrence and abundance of three owl species: the crested owl *Lophostrix cristata* Daudin, 1800, the Amazon pygmy owl *Glaucidium hardyi* Vielliard, 1990, and the tawny-bellied screech owl *Megascops watsonii* Cassin, 1849. We surveyed the owls mostly between 07:00 and 11:00 pm from July 2001 to April 2002, in eighteen 8 km transects along trails at the Ducke Reserve, Manaus, Central Amazon, Brazil. We staked out 50 x 50 m plots where the presence and absence of the owls were recorded. We compared some components of the forest structure between plots where owls were present and plots where they were absent. The spatial variation in these components were related to the occurrence and abundance of the owls using models of multiple logistic and multiple linear regressions analysis, respectively. *Lophostrix cristata* is rare in many other areas of the Amazon forest, but it was the most abundant in our study area. *Lophostrix cristata* and *G. hardyi* were more concentrated along the uplands (central plateau), which divide the reserve into two drainage water-basins. *Megascops watsonii* was distributed mainly in the southeastern part of the reserve. *Glaucidium hardyi* was more often found in areas with larger canopy openness. In areas with higher abundance of snags, there was significantly higher occurrence of *L. cristata* and *M. watsonii*. *Megascops watsonii* was also more abundant in areas with higher abundance of forest trees and in areas bearing shallower leaf litter on the forest floor. This study is the first to analyze at large spatial scale the effects of forest structure on neotropical forest top predator nocturnal birds. The results indicate that forest structure can affect the occurrence and abundance of owls in the Amazon forest.

KEY WORDS. Forest heterogeneity; *Glaucidium*; *Lophostrix*; *Megascops*; nocturnal birds.

In the last four decades forest heterogeneity and habitat structure has been suggested to play a key role in structuring avian communities (MacArthur *et al.* 1966, Karr & Freemark 1983). Some components of habitat structure or floristic composition may determine availability of food, nesting sites, or refuge from predators, and habitat features are considered to be crucial components of birds' niches (Pianka 1974, Wiens *et al*. 1987). Although the effects of habitat heterogeneity on bird populations and communities have received far more attention in temperate regions than in the tropics (Rey 1995 but see Cintra *et al.* 2006, Cintra & Cancelli 2008, Banks-Leite & Cintra 2008), understanding how the structure of tropical forests vary is important to describe the bird assemblages associated to them, and to identify the mechanisms that allow high species coexistence. Tropical forests, however, are a complex environment and detecting exactly what components of the vegetation affect bird distribution and abundance is not trivial.

Human-made disturbed forests are a good example of the importance of forest structure on birds. It has been showed that selective logging produce strong negative effects on the vegetation structure, by reducing or increasing tree density, foliage volume, number of dead trees, amount of leaf litter, and canopy openness (Nepstad *et al.* 1999). Therefore, it is very likely that changes in bird species richness and abundance in disturbed forests are mainly due to changes in some vegetation components, which could affect the availability of food resource and forest microclimatic conditions (Johns 1991, Guilherme & Cintra 2001, Barlow *et al.* 2006). Even primary forests also show a relatively high degree of environmental heterogeneity. The role of this heterogeneity is mostly unexplored, but can also affect the abundance and occurrence of birds and explain why there is such high bird diversity in a given area.

Top predators, such as raptors, are relatively rare in terrestrial bird communities and are dependent on some components of the habitats for their breeding activities (Throstrom *et al.* 2000). Nesting habitats and the number of available prey has been demonstrated to affect population density of some raptor species (Newton *et al.* 1977, van Daele & van Daele 1982). Earlier studies have shown, for instance, that cavities in trees can reduce predation and mortality of young raptors (Bull *et al.* 1989, Belthoff & Ritchinson 1990). For the spotted owl *Strix occidentalis*, nest site location and selection are also related to forest structure, since the mean diameter of trees is greater in nesting sites than in random sites (Hershey *et al.* 1998). Addi-

tionally, owls also use dense vegetation to rest during the warm and hot days (Barrows 1981, Swengel & Swengel 1992) and to hide from their own predators. Finally, owls use vision more than audition to capture their prey (Marks *et al.* 1999) and, therefore, in places where the forest canopy is less dense, more light penetrates to the dark understory, increasing the success of owls in locating and capturing their prey (Call *et al.* 1992).

In the Amazon forest, studies on the effects of forest structure on the distribution and abundance of owls are still scarce. Although basic information on owl species and their habitats are available in few studies (Borges *al.* 2004, Cintra *et al.* 2007) and in some very useful local bird lists (*e.g.* Willis 1977, Terborgh *et al.* 1984, Servat 1996, Zimmer *et al.* 1997, Cohn-Haft *et al.* 1997, Borges 2003), none of these studies include information on how habitat structure affects owl occurrence and abundance. To our knowledge, therefore, the present study is the first to analyze the effects of the Amazon forest structure on owls in a large spatial scale. We investigated how the forest environmental heterogeneity created by the variation in some forest structure components affect the occurrence and abundance of the following three owl species: the crested owl *Lophostrix cristata* Daudin, 1800, the Amazon pygmy owl *Glaucidium hardyi* Vielliard, 1990, and the tawny-bellied screech owl *Megascops watsonii* Cassin, 1849. More specifically, we tested the effects of forest structural components on owl occurrence and abundance in a pristine Central Amazon forest.

MATERIAL AND METHODS

This study was conducted in the Ducke Reserve, near Manaus (02°55'-03°01'S, 59°53'-59°59'W), Amazonas state, Brazil. The reserve has an area of 10,000 hectares, and the mean annual rainfall in the area is 2,286 mm. Most of the rains are concentrated between November and May, and the dry season is between June and October. The soil is mainly oxysol, and small streams are abundant in the area, resulting in a rugged terrain of lowlands intercalated with plateaus reaching an altitude of up to 140 m (Ribeiro *et al.* 1999). There is a large plateau in the middle of the reserve separating two drainage water-basins, one of black water on the west side, and transparent clear water on the east side (Ribeiro *et al.* 1999). The vegetation of the area is mainly primary *terra firme* forest (Ribeiro *et al.* 1999). The reserve is connected to a continuous forest on the east side.

We surveyed the owls by walking slowly (1.5 km/h) and quietly along 18 transects, which were parallel 8 km trails, 1 km apart from one another, nine running east-west and nine north-south, located on a trail grid which covers 6,400 ha of the reserve. All trails are numbered and marked every 100 m. We conducted night surveys for the following species: the crested owl *Lophostrix cristata*, the Amazon pygmy owl *Glaucidium hardyi*, and the tawny-bellied screech owl *Megascops watsonii*. *Lophostrix cristata* is widely distributed in the Americas and probably in the Amazon forest, whereas *G. hardyi* and *M. Watsonii* are widely distributed in the Amazon forest (Hilty 2003).

Methods based on vocalizations have been widely used to estimate occurrence and density of nocturnal raptors, and recording their vocalizations has been the most accurate way of detecting them (Springer 1978, Rocha & Rangel-Salazar 2001). We decided to use a mix of point count and spot mapping techniques, recording owl positions by their vocalizations instead of using playback. These procedures were adopted to reduce the chances of recording the same individuals twice, which would overestimate their density. The surveys were done between July of 2001 and April of 2002, during two weeks a month, mostly under open sky conditions and half to full moon. We did some preliminary surveys that indicated that owls were apparently more active and vocalizing during these two phases of the moon. We spent two weeks a month doing surveys to record the owls, walking 4 km every night from 07:00 to 11:00 pm, and covering all 18 transects in the trail grid (see Fig. 1).

During the surveys, we stopped for two minutes every 100 m along transects to listen, locate, identify and record all owls heard within 50 m on either side of the transects. For each owl detected, we recorded the following information: date and hour, owl species, trail number, and owl position along the trail. Sometimes in the same night and sometimes in the following week while passing through to surveys further blocks, we revisited those 50 x 50 m plots where no owls were detected at least twice to listen and check whether any owls were present. Our index of owl abundance represented the total number of individuals recorded for each species.

We staked out 50 x 50 m plots at each spot where owls were recorded and control plots of same area where owls were absent, located at least 200 m away from plots where owls had been recorded, in order to minimize potential effects of increasing similarity in vegetation structure due to short distances among plots. We used four 50 m metric tapes to mark off the perimeter of the plots within which we recorded the following components of forest structure and landscape: plot distance from the nearest stream, altitude, leaf litter depth, percentage of forest canopy opening, number of logs, number of snags, and number of trees. We believe the variables selected are important because: (a) owls depend on vertical support or three trunks for foraging, therefore areas with more trees could be more attractive to owls; (b) the abundance of logs and snags may provide more area for foraging and nesting; (c) although owls are essentially arboreal, some species capture their prey on the forest floor, therefore, areas with more leaf litter may denounce owl's prey by noise; (d) as the canopy opening increases it allows higher light incidence and illuminates more the forest understory, making potential preys more visible for owls; (e) sites near streams are more humid and may have higher abundance of preys than sites away from streams, and (f) soil components are directly related to altitude, which affect the whole vegetation in the area.

The information on the distance from the nearest streams was obtained from a map of topographic cotes of the Ducke Reserve. The distances were measured using a metric tape marked in centimeters, from the plot's position to the nearest stream,
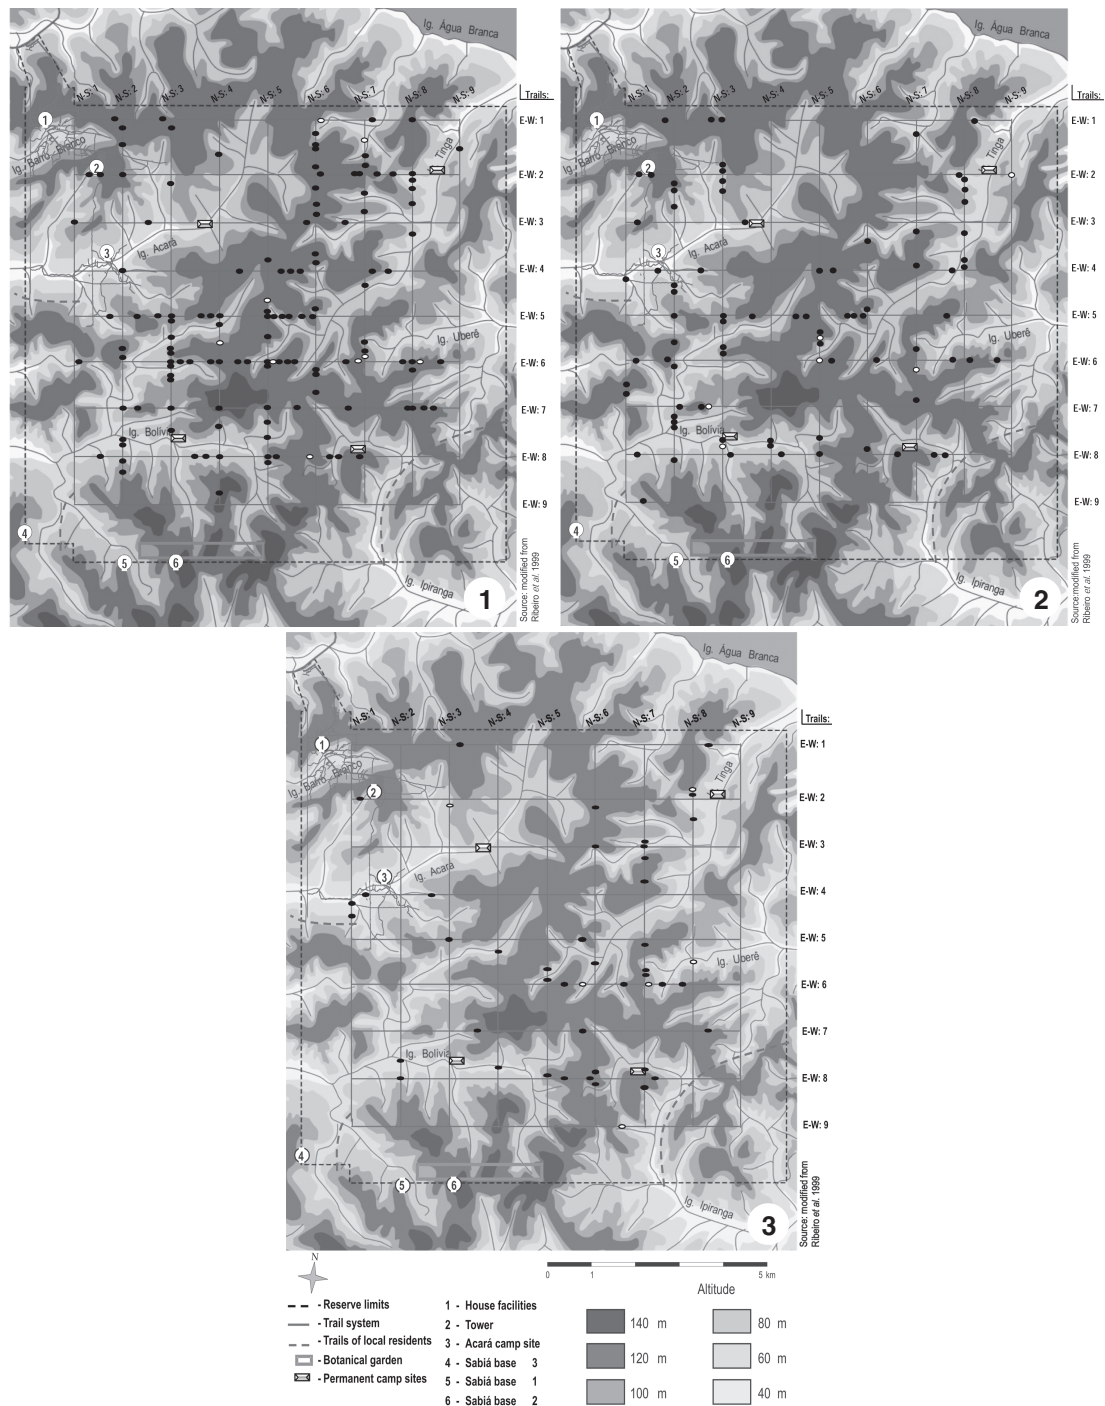

Figures 1-3. Occurrence of individuals of three owl species: (1) the crested owl *L. cristata*; (2) the Amazon pygmy owl *G. hardyi*; (3) the tawny-belied owl *M. watsonii*. Each bird recorded represented by a filled circle along the trail system of Reserva Ducke, Brazilian Amazon.

and converting the distances according to the map scale. Only streams larger than 1 m in width were considered, because the forest is open enough at their banks to permit owls to use or fly along them. Data on altitude were obtained when the trails were open in 1997, and from topographic cotes recorded by a topographic team using theodolite and clinometer.

The leaf litter depth was recorded by inserting a knife blade on the forest floor and counting the number of impaled dead leaves. We recorded the leaf litter layers at the four corners and the center of twenty-one 1 m^2 subplots located 10 m equidistant from one another. Twenty subplots were distributed along the sides, and one was at the center of each 50 x 50 m plot. For the analysis, we used mean values of leaf litter depth per 50 x 50 m plot.

To record variations in the canopy opening, we used a spherical crown densiometer (concave, mode C – Robert E. Lemonn, Forest Densiometer, 5733 SE Cornell Dr. – Bartlesvile, OK, USA). We registered canopy opening four times (one in each direction of the four cardinal points) in each corner and at the center of the 50 x 50 m plots. The raw values recorded in the field were then multiplied by 1.04, as recommended in the technical guide of the spherical crown densiometer. In the analysis, we used the mean values of the percentage of canopy opening per plot.

In the 50 x 50 m plots, we counted all forest logs on the forest floor, which were longer than 1 m and with diameters greater than 20 cm. The total number of logs recorded per plot represented an index of forest log abundance in the analysis. All snags with diameter at breast height (DBH) above 20 cm were counted inside the 50 x 50 m plots. For the analysis, the total number of snags/plot was used as an index of snag abundance. All trees with DBH greater than 15 cm were counted in the 50 x 50 m plots. The reason for measuring only trees with diameter at breast height above 15 cm is that they are large enough for owls to perch, rest or nest. In the analysis, the total number of trees/plot was used as an index of tree abundance.

For each owl species, we ran Pearson correlation matrix analysis to test for correlations among the forest structure components (independent variables). The effects of the forest structure components on the occurrence of owls were evaluated with models of logistic regression using the SYSTAT 8.0 program (WILKINSON 1998). This analysis is indicated in cases where the dependent variable is categorical (owls present = 1 and absent = 0). For this part of the analysis we randomly selected and included 60 records of two owl species (*Lophostrix* and *Glaucidium*) and 30 records of the other species (*Megascops*) corresponding to plots with owls, and 60, 60 and 30 plots without owls, making sample sizes of 120, 120 and 60, respectively.

To analyze the effects of each forest structure component on the abundance of each owl species, we constructed multiple linear regression models, also using the SYSTAT 8.0 program (WILKINSON 1998). Only those 8 km transects which have minimum of one owl were included in the analysis, therefore 16 transects were considered for *Lophostrix* and 17 for *Megascops* and *Glaucidium*. To verify potential problems of residual analysis in multiple regressions we used a graphic method called partial residual plot, available in the statistical program "R". The same program was also used to evaluate multicolinearity. Therefore, to verify possible linear relationships among predicting variables, we estimated the variance inflation factor which calculates the level of multicolinearity (FOX 2002).

RESULTS

Variation in the forest structure components

The mean abundance of forest trees (> 10 cm DAP) was 135.3 (range 62-235), the mean abundance of logs was 11 (range 3 - 38), and the mean abundance of snags was 5.1 (range 0-11). The leaf litter depth ranged from 1.4 to 4.8 layers, and the mean was 3.4 layers. The mean percentage of canopy opening was 9.3% (range 2.6-19.4%). The mean altitude was 75.6 m (range 38.7-114.7 m). The mean distance to the nearest stream was 209.2 m (range 0-571 m). The results of the correlation among all of these variables are presented separately for each owl species in tables I, II, and III, and those significantly correlated were not included together in the same regression models (see below).

Table I. (A) Pearson correlation matrix for the forest structure components recorded in areas with *L. cristata* along the 18 transects of 8 km length at Ducke Reserve, Central Amazon. (B) Pearson correlation matrix for the forest structure components recorded in 120 areas, 60 of them with and 60 without *L. cristata* (see methods). Areas = 50x50 m plots.

$*$ = p < 0.05, $**$ = p < 0.001 resulting from the Bonferroni probability matrix.

Effects of forest structure on the occurrence and abundance of *L. cristata*

Lophostrix cristata was widely distributed in the reserve and throughout most of the eighteen 8 km transects (Fig. 1, Tab. IV). Most of the individuals occurred in the northeastern (33% in the Tinga drainage water-basin) and southwestern (29% in the Bolivia drainage water-basin) parts of the reserve (Fig. 1). The occurrence of *L. cristata* was significantly affected by the abundance of snags and not significantly affected by the rest of the forest structure components (Fig. 4, Tab. V). The abundance of forest trees was significantly correlated to the abundance of logs (see Tab. I), thus these variables were not included in the same regression model together with the others forest components. We then run a separated analysis for the abundance of forest trees and found out no significant effects of this variable on *L. cristata* occurrence (simple logistic regression, MacFadden's Rho-squared ρ^2 = 0.0009, N = 120, T = -1.231, p = 0.218).

The abundance of *L. cristata* varied from 0 to 22 individuals in the 8 km transects (N = 16), and it was not affected by the abundance of forest logs, altitude, leaf litter depth, canopy opening, and tree abundance (Tab. V). However, there was a positive relationship between the abundance of *L. cristata* and abundance of snags, indicating higher concentration of this species in areas with higher abundance of snags (Fig. 5). As stated before, the

Table IV. Abundance of owls surveyed along the eighteen 8 km transects at Ducke Reserve, central Amazon.

T16	11	7	8	26
T17	5	6	6	17
T18	1	0	0	1

abundance of forest trees was significantly correlated to abundance of logs (Tab. I). We then run a separated analysis for the abundance of forest trees and found out no significant effects of this variable on *L. cristata* abundance (simple linear regression, $r^2 = 0.0001$, N = 16, $F_{1,14} = 0.001$, p = 0.992).

Effects of forest structure on occurrence and abundance of *G. hardyi*

Glaucidium hardyi also showed ample spatial distribution in the Ducke Reserve (Fig. 2). The occurrence of *G. hardyi* was not significantly affected by the abundance of snags, distance to the nearest forest stream, abundance of forest logs, leaf litter depth, and altitude (Tab. VI). However, there was a positive and significant relationship between the occurrence of *G. hardyi* and the canopy opening (Fig. 6 and Tab. VI). The abundance of forest trees was significantly correlated to abundance of logs and abundance of snags (see Tab. II), therefore, it was not included in the same regression model together with the others forest components. We then run a separated analysis for the abundance of forest trees and found out no significant effects of this variable on *G. hardyi* occurrence (simple logistic regression, MacFadden's Rho-squared $\rho^2 = 0.0001$, N = 60, T = -0.068, p = 0.946).

We recorded 93 individuals of *G. hardyi* along the eighteen 8 km transects in the reserve, and the abundance ranged from 0 to 11 individuals/8 km transect (N = 17, Tab. IV). None of the forest structure components have significantly affected
Figures 4-5. (4) Descriptive curve generated by the logistic regression showing the relationship between *L. cristata* occurrence and abundance of snags (the results corresponds to that in table V). (5) Partial of multiple linear regressions on *L. cristata* abundance in relation to the abundance of snags. Some numbers in the axes are negative because the partial regression represents the deviation of the expected results if all the other independent variables are kept constant in their observed means. We presented graphs only for those forest components that had significant effects on bird abundance.

the abundance of the *G. hardyi* (Tab. VI). Because the independent variables tree abundance and distance to the nearest stream were significantly correlated with the others as showed by the results of Pearson correlation matrix (Tab. II), we used them in

Table V. Results of the multiple logistic regression for frequency of use (occurrence) of different sites in the forest by *L. cristata* (categorical variable 0 = owl absent, 1 = owl present) and results of the multiple linear regression for owl's abundance in relation to the forest structure components and features of landscape.

Altitude	0.248	16	0.402	0.696
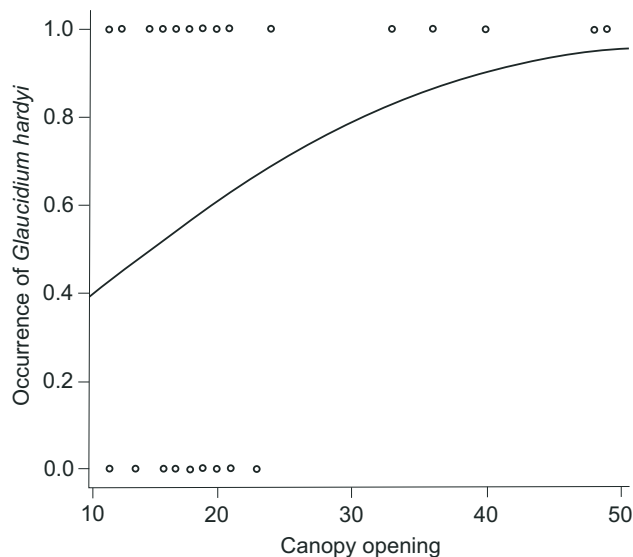

Figure 6. Descriptive curve generated by the logistic regression showing the relationship between *G. hardyi* occurrence and canopy opening (the results corresponds to that in table VI).

two separated simple linear regression models to evaluate their effects on *G. hardyi* abundance. None of them influenced the abundance of *G. hardyi* (tree abundance, $r^2 = 0.171$, N = 17, p = 0.099; distance to the nearest stream, $r^2 = 0.057$, N = 16, p = 0.356).

Effects of forest structure on the occurrence and abundance *M. watsonii*

Most of the 54 individuals of *M. watsonii* (53%) were recorded in the southeastern part of the reserve, which corresponds to the area of Ipiranga water-basin drainage (Fig. 3). Since the independent variable leaf litter depth was significantly correlated to abundance of forest trees and abundance of snags, and altitude was correlated to forest canopy opening (Tab. III), their effects on *M. watsonii* occurrence were analyzed in two separate models (see below). The occurrence of *M. watsonii* was not significantly affected by the abundance of snags, the abundance of trees, the canopy opening, abundance of forest logs, and distance to nearest forest stream (Tab. VII). Note that for this owl species tree abundance and distance to nearest forest stream were not significantly correlated (see Tab. III). Therefore, these variables were included together in the same regression model. However, leaf litter depth was correlated with abundance of trees and snags, and altitude was correlated to forest canopy opening (see Tab. III). Therefore we used leaf litter depth and altitude in separated models, and found out that the occurrence of *M. watsonii* was not significantly affected by the canopy opening ($\rho^2 = 0.006$, N = 30, T = -0.691, p = 0.490) and altitude ($\rho^2 = 0.001$, N = 30, T = -0.200, p = 0.842). The abundance of M. wa*tsonii range*d from 0 to 8 individuals in each 8 km transect (N = 16). Leaf litter depth was significantly correlated to abundance of forest trees and snags, so it was altitude correlated to canopy opening (Tab. III), they were not included in the same regression models with the others forest components (Tab. VII). There were positive rela-

Table VI. tionships between the abundance of *M. watsonii* and the abundance of snags and abundance of forest trees (Fig. 7 and Tab. VII). There was also a negative relationship between the abundance of *M. watsonii* and the leaf litter depth (Fig. 7 and Tab.

VII). However, the abundance of *M. watsonii* was not affected by the canopy opening, abundance of logs, and proximity of streams (Tab. VII). Finally the abundance of *M. watsonii* was influenced by altitude ($r^2 = 0.209$, N = 16, F = 4.240, p = 0.05).
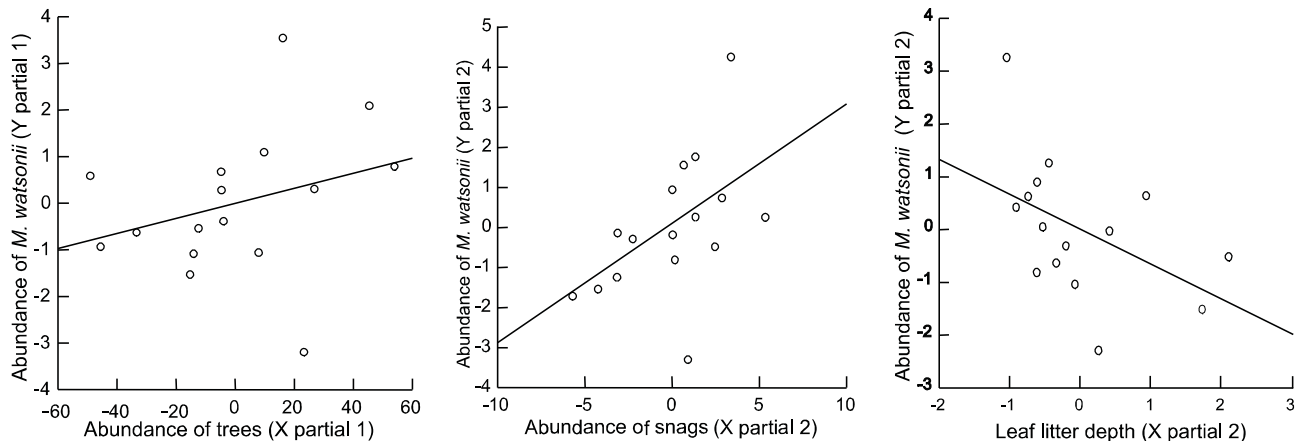

Figure 7. Partials of multiple linear regressions on abundance of the tawny-belied owl *M. watsonii* in relation to abundance of snags, abundance of trees and leaf litter depth. Some numbers in the axes are negative because the partial regression represents the deviation of the expected results if all the other independent variables are kept constant in their observed means. Because we presented graphs only for those forest components that had significant effects on bird abundance and each of them were constructed with data from different multiple regression models with various forest structure components, the number of the partials of the regressions within parenthesis are the same in the two graphs.

DISCUSSION

The results of this study indicate that the environmental heterogeneity produced by isolated or combined effects of forest structural components can influence the occurrence and abundance of some owl species in Central Amazon forest. However, not all owl species were affected in the same way. The crested owl *Lophostrix cristata* occurrence was affected only by the abundance of snags, the Amazon pygmy owl *Glaucidium hardyi* occurrence was affected by the canopy opening, and *M. watsonii* abundance was affected by snag abundance, forest tree abundance, and leaf litter depth (Tabs V-VII, Figs 4-7). On a larger spatial scale, the relief seems to be important for owl occurrence and abundance. Both *L. cristata* and *G. hardyi* occurred mainly along the plateaus of the reserve (Figs 1 and 2). Whether these habitat features (forest structure components and local terrain ruggedness) are considered to be crucial components of birds' niches (PIANKA 1974, WIENS *et al*. 1987) needs further investigation. Nevertheless, other bird species abundance and changes in bird community compositions in relation to changes in the forest structure in Central Amazon forest has also been recently documented (see below, and CINTRA & CANCELLI 2008, BANKS & CINTRA 2008).

Owls generally are opportunistic birds in the use of the resources available, and their frequent use of areas with high abundance of snags may be a consequence of the use of dead or alive trees in their activities (BUCHANAN *et al*. 1993). At Ducke Reserve we found that the abundance of both *L. cristata* and *M. watsonii* was directly related to the abundance of forest snags, suggesting that these owls seem to use preferentially areas in the forest with higher density of snags. Snags can be used by

owls for building nests in natural cavities (BUCHANAN *et al*. 1993). However, the use of snags for nesting is not always favorable. THROSTROM *et al*. (2000) found that species that usually build their nests in cavities of snags are negatively affected by nest predation. The authors suggested that nest predators visit snags more often when they are searching for food. For the screech owl *Megascops asio*, for example, nest cavity dimension is also important since it has been demonstrated that the deeper the nest cavity, the lower the juvenile predation (BELTHOFF & RITCHINSON 1990).

ROCHA & RANGEL-SALAZAR (2001), studying owls in the La Selva Biological, Costa Rica, found that tree density, forest gaps, and proximity to roads were important variables affecting the abundance of vermiculated screech-owl *Megascops vermiculatus* and *L. cristata*. Number of fallen trees was important for the mottled owl *Strix virgata*, and canopy height for the black-and-white owl *S. nigrolineata*. ROCHA & RANGEL-SALAZAR (2001) found that detection of *L. cristata* and *S. virgata* increased in less illuminated areas in the forest. The calling activities of the three owl species were associated with the moon phase, and were also correlated with the season of the year. In our study area, *G. hardyi* seems to prefer more open areas in the forest (Tab. VI, Fig. 6).

Some owls' species may move to other areas when local conditions are limited. For example, the eastern screech owl *Megascops asio* has seasonal habitats, and it has been suggested that this behavior is related to the decrease in the litter depth and fall of leaves, which have a direct effect on the number of cacheable prey (SMITH & GILBERT 1984, SPARKS *et al*. 1994). At Reserva Ducke, the higher abundance of *M. watsonii* in areas of shallow leaf litter may also be related to this owl species' foraging behavior. This species often hunts flying from a perch to

the ground. Because areas of shallow litter tend to have less debris (dead twigs and leaves), the detection and capture of preys on the ground would be easier. For some owls' species in the northern hemisphere, the variation in the amount of ground cover, such as litter and wood debris, was found to be related to the number of the available prey (McInvaille & Keith 1974, Village 1982, Smith & Gilbert 1984, Sparks et al. 1994).

At Ducke Reserve, *M. watsonii* was more often recorded in areas with higher abundance of trees, which seems to contradict the results mentioned earlier, because areas with more trees would be expected to produce more litter fall. However, most of the tree species in our study area are not deciduous during the dry season (Ribeiro et al. 1999). We believe that this owl species is more frequent in areas of higher tree density because they tend to use more closed and shaded areas and tall trees for nest construction and roosting (Marks et al. 1990). In fact, vegetation structure seems to be more important for some owl species to select spots for rest and breeding rather than feeding. For instance, the spotted owl *Strix occidentalis* build their nests in forest areas with higher number of trees and more closed canopy, perhaps to confuse those predators when searching for food in tree cavities (Ganey & Balda 1989, 1994, Call et al. 1992). The long-eared owl *Asio otus* builds its nests in areas with closed canopy, and this behavior seems to reduce predation on their juveniles (Bull et al. 1989). The flammulated owl *Otus flammeolus* in New Mexico prefers areas under lower number of shrubs around the nests; this behavior is consistence with low profile flights close to the ground while tending to the nest (McCallum & Gehlbach 1988).The availability of areas for shelter and rest during the day could be another reason why *M. watsonii* uses areas with higher tree abundance at Reserve Ducke. Individuals of this species use closed and dense forests more often probably because they are more able than other species to fly maneuvers in areas with many obstacles.

Individuals of *M. watsonii* were found in most of the southeastern area of the Reserve (Fig. 3), where the ruggedness of the terrain is accentuated. This is not a particular preference of this species only. In areas of accentuated forest floor inclination, the canopy of a given tree may be closer to the ground than those from plateau areas, and this may help the owl to surprise and, in a short flight, catch more ground preys in these areas. However, this might not be a behavior showed exclusively by tropical owls. In the forested mountains of Arizona, it has been found that spotted owl occurs mainly in forests with closed canopy, which are more common along canyons (Ganey & Balda 1989, 1994).

The availability of preys and their density may affect density and habitat use by many raptors, including the spotted owl *Strix occidentalis* (Carey et al. 1992, Zabel et al. 1995, Ward et al. 1998). In the Amazon forest, Kiltie (1981) found that rodents hide seeds and fruits near forest logs, and often return to the same spots to recover them. The increase in rodent movements around forest logs may attract the attention of owls, which may use the areas more often than those without logs because of the ease of detecting and capturing prey there. Individuals of *G. hardyi* were widely distributed at Reserva Ducke (Fig. 2), and also occurred more often near streams. The use of areas near forest streams by this species could be related to capture of prey. Forest canopy along the streams is more open and may help long flying and gliding movements for locomotion and hunting. At the Reserve, a relatively high number of small, semi-aquatic and terrestrial rodents, birds, frogs, lizards, and other potentials prey are associated with aquatic environments. In Finland, it was found that the high proportion of bodies of water was related to a higher percentage of rodents (*Arvicola terrestris*) in the diet of the Ural owl *Strix uralensis* (Korpimäki & Sulkava 1987).

Finally, our results indicate that the environmental heterogeneity of the forest through its forest structure components at the local and regional levels (large spatial scale) can be determinants to explain the occurrence and abundance of owl species in a given area. We also found that the way habitat structure affects owls was species dependent. Although the forested area of city around the reserve is decreasing every year due to the rapid urban growth of Manaus, we think that the populations of the three owl species seem to be relatively intact. *Lophostrix cristata* may be one of the least known among the 178 species of owl recognized in the world, and in the Amazon region, it is associated with mature forest (*terra firme* forest) for roosting and nesting. However, the protection of the forest in the reserve, through the prevention of human invasion and deforestation, is important, because habitat loss is probably the main factor affecting populations of tropical rain forest birds (Bierregaard & Lovejoy 1989, Johns 1991).
